DNA Structure and Function

In ap biology chapter 17, the structure and function of DNA are central topics. DNA, or deoxyribonucleic acid, serves as the hereditary material in almost all living organisms. Its unique double helix structure, discovered by James Watson and Francis Crick, is composed of two antiparallel strands formed by nucleotides. Each nucleotide consists of a phosphate group, a sugar molecule (deoxyribose), and one of four nitrogenous bases: adenine (A), thymine (T), cytosine (C), and guanine (G). The specific pairing of these bases—adenine with thymine and cytosine with guanine—allows DNA to store genetic information accurately.

Nucleotide Composition

Each nucleotide in DNA is made up of three components: a phosphate group, a five-carbon sugar called deoxyribose, and a nitrogenous base. The nitrogenous bases are divided into purines (adenine and guanine) and pyrimidines (cytosine and thymine). The sequence of these bases encodes genetic information essential for protein synthesis and cellular function.

Double Helix Model

The double helix structure consists of two strands twisted around each other, held together by hydrogen bonds between complementary base pairs. This

configuration provides stability and allows DNA to replicate faithfully during cell division. The antiparallel orientation of strands means one strand runs 5' to 3', while the other runs 3' to 5'.

DNA Replication

DNA replication is a critical process covered extensively in ap biology chapter 17. It ensures that genetic information is accurately copied and passed on to daughter cells during cell division. Replication is semiconservative, meaning each new DNA molecule contains one original strand and one newly synthesized strand.

Key Enzymes Involved

Several enzymes facilitate DNA replication, including helicase, DNA polymerase, primase, and ligase. Helicase unwinds the double helix, creating a replication fork. DNA polymerase adds nucleotides to the growing strand in a 5' to 3' direction, using the original strand as a template. Primase synthesizes RNA primers to initiate replication, while ligase joins Okazaki fragments on the lagging strand.

Leading and Lagging Strands

Replication occurs differently on each strand due to the antiparallel structure. The leading strand is synthesized continuously toward the replication fork, whereas the lagging strand is synthesized discontinuously away from the fork in short segments called Okazaki fragments. These fragments are later connected by DNA ligase.

Gene Expression: Transcription and RNA Processing

Gene expression begins with transcription, the process by which DNA is copied into messenger RNA (mRNA). This step is vital for transferring genetic information from the nucleus to the cytoplasm, where proteins are synthesized. Ap biology chapter 17 explains the stages of transcription and the modifications that mRNA undergoes before translation.

Transcription Process

During transcription, RNA polymerase binds to a promoter region on the DNA and synthesizes a complementary RNA strand by matching RNA nucleotides to the DNA template strand. Unlike DNA, RNA contains uracil (U) instead of thymine. Transcription proceeds through initiation, elongation, and termination phases to produce a primary RNA transcript.

RNA Processing in Eukaryotes

In eukaryotic cells, the primary RNA transcript undergoes processing before becoming mature mRNA. This includes the addition of a 5' cap, a poly-A tail at the 3' end, and splicing to remove non-coding sequences called introns. The remaining coding sequences, exons, are joined together to form a continuous sequence that will be translated into protein.

Translation and Protein Synthesis

Translation is the process by which the mRNA sequence is decoded to build a polypeptide chain or protein. This phase of gene expression occurs in the cytoplasm and involves ribosomes, transfer RNA (tRNA), and various translation factors. Ap biology chapter 17 details the mechanisms and stages of translation.

Role of Ribosomes and tRNA

Ribosomes are molecular machines that facilitate the binding of tRNA to mRNA. Each tRNA molecule carries a specific amino acid corresponding to its anticodon, which pairs with a complementary codon on the mRNA. This ensures the correct sequence of amino acids in the growing polypeptide chain.

Stages of Translation

Translation occurs in three main stages: initiation, elongation, and termination. During initiation, the ribosome assembles around the mRNA and the first tRNA. Elongation involves the sequential addition of amino acids as the ribosome moves along the mRNA. Termination happens when a stop codon is reached, signaling the release of the completed polypeptide.

Regulation of Gene Expression

Regulation of gene expression allows cells to respond to environmental signals and maintain homeostasis. Ap biology chapter 17 addresses the mechanisms that control when and how genes are expressed, including transcriptional and post-transcriptional controls.

Operons in Prokaryotes

In prokaryotes, gene expression is often regulated by operons, which are clusters of genes controlled by a single promoter and operator. The lac operon and trp operon are classic examples that demonstrate inducible and repressible systems, respectively. These operons allow bacteria to adapt to the availability of nutrients by turning genes on or off as needed.

Gene Regulation in Eukaryotes

Eukaryotic gene regulation is more complex and involves multiple levels,

including chromatin remodeling, transcription factors, and RNA interference. Chromatin structure influences gene accessibility, while transcription factors activate or repress gene transcription. Additionally, small RNAs can modulate gene expression post-transcriptionally.

Experimental Evidence and Historical Context

Ap biology chapter 17 also reviews key experiments that established the molecular basis of inheritance. Understanding these historical milestones provides insight into how current knowledge was developed.

Griffith's Transformation Experiment

Frederick Griffith's experiment with *Streptococcus pneumoniae* demonstrated the phenomenon of transformation, suggesting that a "transforming principle" could transfer genetic information between bacteria.

Avery-MacLeod-McCarty Experiment

This experiment identified DNA as the transforming principle, providing strong evidence that DNA is the genetic material rather than proteins or RNA.

Hershey-Chase Experiment

Using bacteriophages, Hershey and Chase confirmed that DNA, not protein, is the genetic material transmitted to progeny, solidifying DNA's role in heredity.

Meselson-Stahl Experiment

The Meselson-Stahl experiment demonstrated the semiconservative nature of DNA replication, a fundamental concept explained in ap biology chapter 17.

Summary of Key Experiments

- Griffith's transformation and discovery of genetic transfer
- Avery-MacLeod-McCarty identification of DNA as genetic material
- Hershey-Chase confirmation of DNA's role in heredity
- Meselson-Stahl demonstration of semiconservative replication
